The electronic band structure of armchair carbon nanotubes may be considerably modified by potentials with angular dependence. Different angular modes \( V_q \sim \cos q \theta \) have been studied within a tight-binding scheme. Using symmetry arguments, we demonstrate a bandgap opening in these metallic nanotubes when certain selection rules are satisfied for both potential and nanotube structure. We estimate the bandgap opening as a function of both the external potential strength and the nanotube radius and suggest an effective mechanism of metal-semiconductor transition by combination of different forms of perturbations. © 2004 American Institute of Physics.

[DOI: 10.1063/1.1811792]

Armchair single-wall carbon nanotubes (SWNTs) with indices \((n,n)\) are metallic with two subbands crossing at the Fermi level, which is allowed by opposite parities of these two subbands with regard to the \(n\) vertical mirror reflections \(\sigma_v\). It is interesting to explore if one can break the mirror symmetry and generate a bandgap by choosing appropriate angular perturbations, so that one can modify and control nanotube material properties for applications. It was recently proposed to use a very inhomogeneous electric field to induce metal-semiconductor transition (MST) in armchair SWNTs.\(^5\) Other types of circumferential perturbations were studied including in-rapeto interaction,\(^2\) twisting or bending,\(^3\) squashing\(^4\)-\(^7\) and applying uniform perpendicular electric fields.\(^8,9\) Some perturbations indeed were found to induce MST, which was attributed partially to the breaking of SWNT mirror symmetry. However, there still remains an open question if mirror symmetry breaking (MSB) is a sufficient condition to bring in a bandgap in armchair tubes. For example, in the case of bending or applying a uniform electric field, by rotating the armchair nanotube, one can always find an alignment that breaks all vertical mirror symmetries but the nanotube remains metallic, which cannot be explained by the MSB argument alone.

In this letter, we apply potentials with angular dependence to modulate the band structure and electronic properties of the armchair SWNTs. We choose angular modes \( V_q = V_0 \cos q \theta \) or their combinations to study gap opening within an orthogonal \( \pi \)-orbital tight-binding (TB) scheme. We found that (1) breaking symmetries about all the vertical mirror planes \( \sigma_v \) and \( C_2 \) rotations (see below) is required to mix the two linear subbands near the Fermi level; (2) selection rules of subband coupling impose additional requirement on the angular momentum of the perturbation, e.g., a single mode with odd \( q \) does not generate any bandgap; (3) for modes with even \( q \), MST is only possible for tubes with specific indices \( n \) to satisfy selection rules described below.

Selection Rules. The symmetry group of a \((n,n)\) armchair SWNT consists of vertical mirror planes \(\sigma_v\), horizontal mirror planes \(\sigma_h\) and rotation axes \(C_2 = \{U, U'\}\) (Fig. 1). Every electron state can be labeled by a set of quantum numbers: an axial wave number \( k \), an angular quantum number \( m \), a parity with regard to the vertical mirror reflection \(\sigma_v(A/B)\) and a parity to the horizontal mirror reflection \(\sigma_h(+/\sim)\). There are also two sets of \( C_2 \) axes \( U \) and \( U' \), which are perpendicular to the tube axis. The two linear subbands \( |\pi\rangle \) and \( |\pi'\rangle \), both have \( m = n \) and even parities about \(\sigma_v \) while their parities about \( U \) and \( U' \) and \(\sigma_h \) are opposite.\(^10\) It is the different parities that allow the two subbands to cross and be degenerate at the Fermi points. We do not consider potentials with an axial space dependence, thus, the quantum number \( k \) is conserved.

What are the symmetry conditions required for MST in armchair nanotube? **Rule 1:** All symmetries about vertical mirror planes \(\sigma_v\) and \( C_2 \) axes \( U \) and \( U' \) must be broken simultaneously.

The selection rules of subband coupling impose additional requirement on the angular quantum number of the potential as well as the nanotube indices. Assume that the external potential has only one angular mode \( V_q(\theta) \sim \cos q(\theta + \theta_0) \), where an arbitrary offset \( \theta_0 \) is zero when a mirror plane of the potential coincides with the one of the

FIG. 1. Left: Symmetry operations of a \((n,n)\) armchair nanotube. Right: Unwrapped unit cell of a \((5,5)\) nanotube and schematics of an external potential of the form \( V = V_0(\sin \theta + \sin 2\theta) \).
SWNT. The conservation of total quantum numbers \( k \) and \( m \) imposes the selection rules for direct subband coupling in a \((n,n)\) SWNT: \( \delta k = 0 \) and \( \delta m = \pm q + 2nj \), with \( j \) an integer. The indirect interaction between \(|\pi\rangle\) and \(|\pi^*\rangle\) states \( H_{\pi\pi^*} \) can thus be represented by a Feynman-like diagram, or as a perturbation series of the coupling order \( \mu \) [Fig. 2(a)]. Here all allowed intermediate states \( \{m_i,s_i\} \) are states of the given angular momentum \( m \) and pseudo-spin \( s \), with \( s = \pm 1 \) denoting the conduction and valence bands, respectively. Due to the symmetry of electron and hole bands, contributions of even \( \mu \) cancel out as shown in Fig. 2(b) (a detailed example will be shown below). Thus, only for odd coupling order \( \mu \), there can be a nonvanishing coupling between \(|\pi\rangle\) and \(|\pi^*\rangle\) states. The most important contribution comes from the lowest possible \( \mu \) which is \( \mu_0 = 2n/gcd(2n,q) \), where \( gcd \) is the greatest common divisor. We formulate the second rule for the MST in the single mode angular potential \( V_q \).

**Rule 2:**

\[
\mu_0 = \frac{2n}{gcd(2n,q)} = \text{odd}.
\]

One conclusion we can draw immediately is that there is no MST when \( q \) is odd, because then \( \mu_0 \) is even, which violates rule 2. This is consistent with the absence of the bandgap for armchair SWNTs under a uniform perpendicular electric field, i.e., \( q = \pm 1 \).

By nearly degenerate perturbation theory, we derive the dependence of the bandgap opening on the angular offset \( \theta_0 \). We already know that when \( \theta_0 = 0 \), there shall be no bandgap according to rule 1. By changing the relative alignment of the SWNT and the potential, a bandgap starts to develop and \( E_g \) can be estimated as

\[
E_g(\theta_0) = E_g^{\text{max}} \sin(\mu_0 \theta_0).
\]

It is self-evident that the maximum of the bandgap is for \( \theta_0 = \pi/(2\mu_0 q) \) when \( V_q \) is so aligned that the potential is antisymmetric about one of the vertical mirror planes.

The case with \( q = 2 \) is reminiscent of squashing an armchair SWNT. Our analysis explains why a small bandgap was found in a \((5,5)\) SWNT in Ref. 4 but not in \((6,6)\) SWNT in Ref. 6 or \((8,8)\) SWNT in Ref. 7. Since \( \mu_0 = n \) for \( q = 2 \), only SWNTs with odd \( n \) can open a bandgap. In \((8,8)\) and \((6,6)\) armchair nanotubes there should be no mixing between the crossing subbands. For odd \( n \), the bandgap opening is roughly \( E_g \propto V_0^2 \sin(2n\theta_0) \) and decreasing for large radius nanotubes due to the higher order of perturbation. The maximum bandgap of a \((5,5)\) SWNT by the \( q = 2 \) potential is of the order of 0.1 eV within our TB calculation.

The most interesting case for potential applications is that the potential has short oscillation period: \( q = 2n \), which yields direct mixing to the coupling order \( \mu_0 = 1 \). Assuming no overlap between orbitals on different atomic sites, an analytical expression for the bandgap can be obtained by the degenerate perturbation theory

\[
E_g = \sqrt{3}V_0 \sin(2n\theta_0),
\]

Since \(|\pi\rangle\) and \(|\pi^*\rangle\) are now directly coupled, the bandgap is proportional to the perturbation and the relation in Eq. (2) holds up to a few eV. Potential of this form \( (q = 2n) \) requires changing the sign of the electrostatic potential alternatively on neighboring carbon atoms. One can possibly generate such perturbations by twisting, chemical/biological decoration of the tube or by using the high multipoles of very inhomogeneous potential.

The potential with mixed Fourier components. Realistic perturbations usually have more than one dominating angular mode, which makes analytical expressions tedious. On the other hand, the interplay of the different angular components may result in stronger and more interesting perturbation of the electronic properties of the SWNTs. For example, the transport behavior of a deformed nanotube may change under the control of the gate potential.11 When the strength of the field across the SWNT is large, the gate potential shifts the Fermi level and also modifies the band structure. In the simplest case, only two angular components are present: \( H_1 = V_1 \cos(\theta + \theta_1) + V_2 \cos[2(\theta + \theta_2)] \). Here \( \theta_1 \) and \( \theta_2 \) are defined as the angular offsets of the mirror planes of \( V_1 \) and \( V_2 \) with regard to that of the SWNT.

The coupling order \( \mu_0 \) is now a function of both \( q_1 \) and \( q_2 \). For \( q_1 = 1, q_2 = 2 \), the lowest allowed coupling is of the third order through \(|\pi\rangle \leftrightarrow |m_1,s_1\rangle \leftrightarrow |m_2,s_2\rangle \leftrightarrow |\pi^*\rangle \) and there are 24 possible sets of intermediate states \( \{m_1,s_1; m_2,s_2\} \)

\[
\begin{align*}
(m_1,m_2) = &\left\{(\pm 1, \mp 1), \right.
\item \left. \{\pm 1, \pm 1\} \right) \oplus \left( s_1,s_2 \right) = \left(\pm 1, \mp 1\right) \oplus \left(s_1,s_2 \right) = \left(\pm 1, \pm 1\right),
\item \left(\pm 1, \pm 1\right) \oplus \left( s_1,s_2 \right) = \left(\pm 1, \mp 1\right).
\end{align*}
\]

Here \( m_1,m_2 = \pm 1, \pm 2 \) are the quantum numbers relative to \( m = n \). In general case, the bandgap opening is related to the off-diagonal element \( H_{\pi\pi^*} \) in the \( 2 \times 2 \) matrix of \( \pi \) and \( \pi^* \) states, which can be written via contributions from different intermediate sets \( \{i\} \mapsto \{m_i,s_i\} \)

\[
H_{\pi\pi^*}^{(\mu)}(i) = \frac{\langle \pi|H_{1}|1\rangle \langle 1|H_{1}|i+1\rangle \langle i+1|H_{1}|\pi^*\rangle}{[E_0 - E(1)] \cdots [E_0 - E(\mu - 1)]},
\]

\[
H_{\pi\pi^*} = \sum_{\{m_i,s_i\}} H_{\pi\pi^*}^{(\mu)}(i),
\]

where \( E_0 = 0 \) for symmetric \( \pi \) and \( \pi^* \) bands and \( E(i) \) is the eigenenergy of the electron state \( |i\rangle \).

The matrix element \( \langle V\rangle = \langle i|V_q \cos(q(\theta + \theta_0))|i+1\rangle \) can be simplified by neglecting the coupling between sublattices in an envelope function approximation

\[
\langle V\rangle = \delta_{m,n,q} V_0 \frac{1}{4} e^{i\Delta m\theta_0} (1 + s_1 s_2 + e^{i(\phi_{m_1}-\phi_{m_2})}),
\]

\[
e^{i\phi_{m_2}} = C_m^A(k)e^{ik_m(k)},
\]

where \( \Delta m = m_1 - m_{i+1} \) and \( C_m^A(k) \) are the coefficients of the Bloch components on A and B sublattices in the electronic wave functions. Since one is mostly interested in the properties of electronic states near the Fermi level, nearly degeneracy...
up, we can get the analytical expression for the bandgap at characteristic energy spacing between subbands. Substituting should notice that which decays with the inverse square of the radius. One order of a secondary bandgap in quasimetallic SWNTs, defined as

$\Delta E_g = V_0 - 2 V_{10}$

$E_{g}$ is related to the relative angle $\theta_{12}$ and the dimensionless potential $\delta$ is defined as $(V_0^2/V_{10})^{1/2}$. The $R^{-2}$ dependence makes $E_g$ of the order of a secondary bandgap in quasimetallic SWNTs, which decays with the inverse square of the radius. One should notice that $E_g$ is only related to the relative angle $\theta_{12}$: When $\Delta \theta_{12} = 0$, the mirror planes of the two components coincide and perturbation theory predicts no bandgap whether or not the total potential breaks the mirror symmetry. The maximum bandgap happens at $\Delta \theta_{12} = \pm \pi/4$, which corresponds to the configuration that the nodes of the two potential components overlap, as confirmed by numerical TB results when $n \gg 5$ (Fig. 3). Since this combination ($q_1 = 1$ and $q_2 = 2$) always gives a secondary bandgap unless $\Delta \theta_{12} = 0$, which can be tens or hundreds of meV for SWNTs with a moderate radius, it may be an effective mechanism to induce MST in armchair nanotubes and put them into tunable metallic field-effect transistors.\(^1\)

In conclusion, we derived the selection rules for the metal-semiconductor transition of armchair SWNTs under an external circumferential perturbation within the orthogonal $\pi$-orbital TB scheme. We evaluated the bandgap opening as a function of the external potential strength and its angular alignment with SWNT mirror planes. Combinations of perturbations of different angular modes are shown to open the gap up to 0.1 eV for (6,6) SWNT and may represent an effective mechanism of the metal-semiconductor transition.
